Zh. Eksp. Teor. Fiz. **59**, 1049-1055 (October, 1970)

The Wolfenstein parameter  $A$  and the polarization  $P$  in  $pn$  scattering at 605 MeV were measured at angles  $55^\circ$ ,  $78^\circ$ ,  $94^\circ$ , and  $125^\circ$  (c.m.s.). The results (Table I) were used to refine two existing sets of phase shifts from the phase shift analysis of  $NN$  scattering at 630 MeV<sup>[6]</sup>. Using the  $\tau$  test<sup>[14,15]</sup>, the probability of an error of the first kind is estimated if the solution with the large  $\chi^2$  (solution II from<sup>[6]</sup>) is discarded; this error turned out to be  $\alpha < 0.01\%$ .

THE amplitude for elastic scattering of nucleons by nucleons at energies 50-400 MeV was uniquely determined within the framework of the phase-shift analysis<sup>[1]</sup>. Above the threshold of meson production, when this process begins to play an important role in  $NN$  interaction, the energy interval closest to the non-ambiguity region and most thoroughly investigated experimentally is the one from 600 to 650 MeV. A phase-shift analysis referred to the energy 630 MeV and valid, accurate to within the method used to take inelastic processes into account, was carried out in this case many times<sup>[2,3]</sup>. As data accumulated in accordance with the previously mentioned program<sup>[4]</sup> and as statistical selection criteria<sup>[5]</sup> more stringent than the  $\chi^2$  criterion were introduced, the number of solutions decreased continuously. At the present there are two known sets of phase shifts that describe the results of the experiments equally well<sup>[6]</sup>. These sets have made it possible to plan further experiments for the purpose of eliminating the existing ambiguities. Prevalent among these is the measurement of the Wolfenstein parameter  $A$  in  $pn$  scattering, since the angular dependences of this parameter, calculated on the basis of the indicated sets of phase shifts, differ noticeably from each other (Fig. 1). This circumstance, and also the fact that this parameter was not measured earlier in the investigated energy interval, stimulated the performance of the experiment described below.

#### EXPERIMENT

The scattering cross section  $I_2$  and the polarization  $\langle \sigma \rangle_f$  of a beam of particles with spin 1/2, after scattering by an unpolarized target with spin 1/2 are given by

Table I

	$\vartheta$ (c.m.s.)			
	$55^\circ$	$78^\circ$	$94^\circ$	$125^\circ$
$A_{pn}$	$0.88 \pm 0.18$	$0.64 \pm 0.20$	$0.75 \pm 0.14$	$0.70 \pm 0.21$
$P_{pn}$	$0.11 \pm 0.06$	$-0.15 \pm 0.07$	$-0.23 \pm 0.04$	$-0.30 \pm 0.08$
Number of events	12532	5262	11386	10950

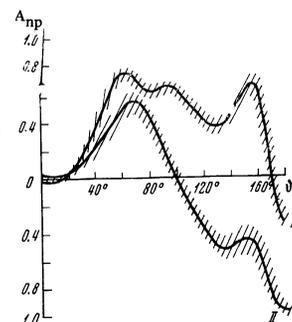

FIG. 1. Angular dependence of the Wolfenstein parameters  $A_{np}$  calculated from the phase-shift sets II and III of [7]. The hatched regions indicate the error corridors.  $\vartheta$  is the scattering angle in the c.m.s.

the well known Wolfenstein formula<sup>[7]</sup>\*

$$I_2 \langle \bar{\sigma} \rangle_f = I_{02} \{ (P_2 + DP_1 n_2) n_2 + (AP_1 k_2 + RP_1 [n_2 k_2]) S_2 + (A'P_1 k_2 + R'P_1 [n_2 k_2]) k_2' \},$$

where  $P_1$  is the initial polarization of the beam;  $k_2$  and  $k_2'$  are unit vectors in the direction of the momentum before and after the scattering;  $n_2$  is the normal to the scattering plane;  $P_2$  is the polarization occurring when an unpolarized beam is scattering;  $S_2 = n_2 \times k_2'$ ;  $A$ ,  $D$ ,  $R$ ,  $A'$  and  $R'$  are the Wolfenstein parameters;  $I_{02}$  is the cross section for the scattering of the unpolarized beam.

\*  $[n_2 k_2] \equiv n_2 \times k_2$ .

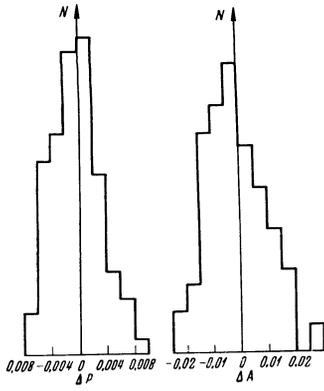

FIG. 3. Errors introduced in the determination of the parameters P and A by the inaccuracy of measurement of the angle of scattering by the analyzer and the spark chambers. The histograms were obtained by the Monte Carlo method. N is the number of events.

tering were calculated from the formulas

$$A_{pn} = (A_{CD_2} - KA_{CH_2}) / (1 - K),$$

$$P_{pn} = (P_{CD_2} - KP_{CH_2}) / (1 - K),$$

where K is the ratio of the number of events from a CH<sub>2</sub> target to the number of events from a CD<sub>2</sub> target, normalized to an equal number of monitor counts. The value of K turned out to be 0.26 ± 0.01, 0.23 ± 0.01, 0.25 ± 0.01, and 0.26 ± 0.01 for the angles 55, 78, 94, and 125°, respectively. Table I gives the values of A<sub>pn</sub> and P<sub>pn</sub> obtained as a result of the reduction of

40,130 events. Approximately one-quarter of all the events pertains to the measurement of the background (CH<sub>2</sub> or C).

In addition to the statistical errors, there are also errors in the determination of P<sub>1</sub> and P<sub>3</sub>; the latter were taken into account during the reduction process by the maximum-likelihood method. The contribution due to the inaccuracies in the measurement of the projections of the scattering angle φ<sub>3</sub>, which has a normal distribution, as established by two independent scanings, was estimated by the Monte Carlo method. To this end, the distribution of I<sub>3</sub>(φ<sub>3</sub>, φ<sub>3</sub>) was generated at A = 0 and P<sub>2</sub> = 0 (10,000 events) with the same dependence on φ<sub>3</sub> as obtained in the experiment. This distribution was then deformed in each test in accordance with the algorithm

$$\left. \begin{matrix} \theta_1^i \\ \theta_2^i \end{matrix} \right\} \rightarrow \left. \begin{matrix} \theta_1^i \\ \theta_2^i \end{matrix} \right\} \rightarrow \left. \begin{matrix} \theta_1^i + \eta_j \Delta\theta \\ \theta_2^i + \eta_{j+1} \Delta\theta \end{matrix} \right\} \rightarrow \left. \begin{matrix} \theta_1^i \\ \theta_2^i \end{matrix} \right\}$$

where Δθ = 0.7° is the variance in the distribution of the measurement error of the projections of θ<sub>1</sub> and θ<sub>2</sub>; η<sub>j</sub> are random numbers with a normal distribution and unity variance; i assumed values from 1 to 10,000 and j from 1 to 20,000 n, where n is the number of tests. For a distribution deformed in this manner we determined each time the parameters A and P<sub>2</sub>. The distributions of A and P<sub>2</sub>, obtained after 100 tests, are shown in Fig. 3. We see that their variances do not exceed 0.015 and 0.004, respectively.

CONCLUSION

The obtained values of A<sub>pn</sub> and P<sub>pn</sub> were used to refine the phase-shift sets obtained in<sup>[6]</sup>. We included additionally in the analysis the data on the total cross

Table II. Phase-shift sets II and III after their refinement (Stapp parametrization)

section of the elastic interaction σ<sub>tot</sub><sup>in</sup>, which is equal to

$$\sigma_{tot}^{in} = \frac{\pi}{2k^2} \sum_L \sum_J (2J + 1) (1 - \exp\{-4 \text{Im} \delta_{LJ}\}).$$

This expression is valid with the same accuracy that the factor cos<sup>2</sup> 2ε<sub>2</sub> (ε<sub>2</sub> ~ 3°) can be replaced by unity in front of the terms of the sum corresponding to the mixing states <sup>3</sup>P<sub>2</sub> and <sup>3</sup>F<sub>2</sub>. The two sets were refined by independently varying the imaginary parts of the phase shifts for the states <sup>3</sup>P<sub>0,1,2</sub>, <sup>1</sup>D<sub>2</sub>, and <sup>3</sup>F<sub>2,3,4</sub>. It turned out that Im δ<sub>3P<sub>0</sub></sub> and Im δ<sub>3P<sub>1</sub></sub> go off during the course of

minimization of the functional χ<sup>2</sup> into the unphysical region (they become negative). In this case they were assumed equal to zero and their values fixed.

During the course of the refinement we found that the aggregate of the experimental information on NN scattering in the energy interval 600–650 MeV is described by the phase-shift sets III and II from<sup>[6]</sup>, with χ<sup>2</sup> values 198.5 and 248.3, respectively, and with χ<sup>2</sup> = 191. The contribution made to Δχ<sup>2</sup> = χ<sup>2</sup><sub>II</sub> - χ<sup>2</sup><sub>III</sub> = 49.8 from the values of A<sub>pn</sub> measured in the present experiment is 31.2.

Using the τ-test<sup>[14]</sup> as applied to the phase-shift analysis<sup>[15]</sup>, we estimated the probability of an error of the first kind with the solution with large χ<sup>2</sup> (set II) discarded. It turned out to be α < 0.001%. Thus, assuming that the elastic part of the NN-scattering amplitude for the states with L > 5 is described satisfactorily by a one-meson Feynman diagram and that the meson production proceeds mainly from the states <sup>3</sup>P<sub>0,1,2</sub>, <sup>1</sup>D<sub>2</sub>, and <sup>3</sup>F<sub>2,3,4</sub>, the solution II can be discarded. However, as already mentioned earlier<sup>[16]</sup>, the conclusion that the phase-shift analysis is single-valued in the investigated energy region depends to a considerable degree on

If we choose the experimental conditions such that  $\mathbf{P}_1 \parallel \mathbf{k}_2$ , then, recognizing that  $\mathbf{P}_1 \perp \mathbf{P}_2$  and that  $I_2 = I_{02}(1 + \mathbf{P}_1 \mathbf{P}_2)$  implies  $I_2 = I_{02}$ , we obtain

$$\langle \bar{\sigma} \rangle = P_2 \pm P_1 A S_2 \pm P_1 A' k_2'$$

After the succeeding, analyzing scattering, the angular distribution of the scattered particles is

$$I_3 = I_{03}(1 + \langle \bar{\sigma} \rangle P_3)$$

or

$$I_3(\vartheta_3, \varphi_3) = I_{03}(\vartheta_3) \{1 + P_3(\vartheta_3) \times [P_2(\vartheta_2) \cos \varphi_3 \pm A(\vartheta_2) P_1 \sin \varphi_3]\}.$$

Here  $\vartheta_3$ ,  $\varphi_3$ ,  $P_3(\vartheta_3)$ , and  $I_{03}(\vartheta_3)$  are respectively the polar and azimuthal angles, the analyzing ability, and the cross section for scattering of the unpolarized beam by the analyzer,  $\varphi_3$  is the angle between  $\mathbf{S}_2$  and the plane of the analyzing scattering, reckoned from  $\mathbf{S}_2$  to  $\mathbf{P}_3$ . The signs plus and minus correspond to antiparallel or parallel mutual orientation of the vectors  $\mathbf{P}_1$  and  $\mathbf{k}_2$ .

By measuring the cross section  $I_3(\vartheta_3, \varphi_3)$  we can determine the parameter of interest to us either from the "up-down" asymmetry or by using the maximum-likelihood method<sup>1,8,9</sup>.

The experiment was performed with a longitudinally polarized proton beam from the JINR synchrocyclotron<sup>10,11</sup>. The beam polarization was  $0.34 \pm 0.02$ , the average energy was  $605 \pm 9$  MeV. At scattering angles 55, 78, 94, and 125° (c.m.s.), corresponding to the elastic kinematics of scattering of free nucleons by nucleons, we measured the difference of the effects from targets made of CD<sub>2</sub> and CH<sub>2</sub> with equal numbers of carbon nuclei. The spin state of the scattered proton beam was analyzed by scattering by carbon plates placed inside optical spark chambers. The analyzer thicknesses were chosen such that the angle of multiple scattering in them did not exceed 2°, and amounted to  $(9.5 \pm 9.5)$  g/cm<sup>2</sup> for scattering angles 55, 78, and 94° and  $(5.7 + 4.8)$  g/cm<sup>2</sup> for the angle 125°. The photography was in two mutually perpendicular planes. The construction of the setup (Fig. 2) has made it possible to perform measurements simultaneously at two angles.

The separation of the acts of elastic pn scattering and control of the operation of the spark chambers was with the aid of scintillation counters connected in accordance with the schemes  $C_1 + C_2 + H_1 - A_1$  and  $C_3 + C_4 + H_2 - A_2$ , respectively, for one and the other scattering angle, where  $C_1, C_2, C_3$ , and  $C_4$  are counters registering the scattered protons,  $H_1$  and  $H_2$  are the neutron counters installed at conjugate angles, and  $A_1$  and  $A_2$  are anticoincidence counters which eliminate registration of pp scattering. The angular resolution of the proton branch was  $\pm 1^\circ$  for the angles 55, 78, and 94° and  $\pm 1.5^\circ$  for 125°. The efficiency of the neutron counters was approximately 10%. Anticoincidence-channel operation was monitored by additional spark chambers placed ahead of the neutron counters.

## DATA REDUCTION

In reducing the spark-chamber photographs we used the following selection criteria:

1) The presence of a single track in the main chamber and its absence in the control chamber;

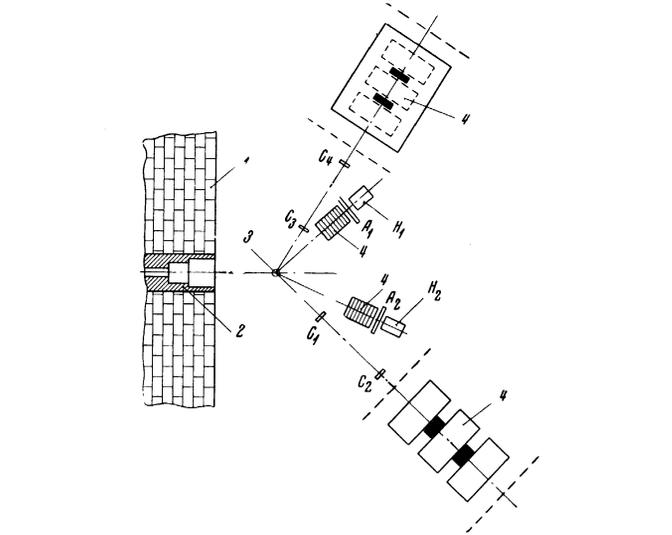

FIG. 2. Experimental setup: 1) Shield, 2) collimator, 3) scatterer, 4) spark chambers,  $C_1 - C_4$ ) proton counters,  $H_1, H_2$ ) neutron counters,  $A_1, A_2$ ) anticoincidence counters.

2) a kink in the track corresponds to the position of the analyzer (and not of the chamber electrodes);

3) the events to be measured are those in which the sum of the projections of the scattering angle is larger than 3° ( $\theta_1 + \theta_2 > 3^\circ$ ).

During the stage of the preliminary computer reduction, initial requirements were imposed:

a) The deviation of the direction of entry of the particle into the chamber from the direction averaged over the nearest 200 events should not exceed the angle  $\Delta\vartheta = 4.5^\circ$  determined by the geometry of the experiment.

b) The analyzing-scattering angle  $\vartheta_3 \geq 6^\circ$ .

The first of these requirements excludes registration of charged particles not arriving from the target. The second requirement establishes the lower limit with respect to  $\vartheta_3$ , at which the reduction yields results that are stable within the limits of errors.

The final reduction of the events satisfying the indicated criteria was carried out by the maximum-likelihood method. The likelihood function was written in the form

$$L = \prod_i \{1 + P_3(\vartheta_3^i) [P_2(\vartheta_2^i) \cos \varphi_3^i \pm P_1 A(\vartheta_2^i) \sin \varphi_3^i]\}.$$

Measurements with different mutual orientations of the vectors  $\mathbf{P}_1$  and  $\mathbf{k}_2$  (the signs +, -) make it possible to exclude the possible systematic errors connected with the adjustment of the apparatus and with the systematic errors in the measurement of the projections of the scattering angles on the photographs.

The analyzing ability  $P_3(\vartheta_3)$  in the reduction of the information for the angle 125° was taken to be the polarization produced in scattering of protons by carbon, averaged over the energy<sup>10,11,13,1</sup>. The basis for this was the good agreement between the angular distributions of the pC scattering, measured in our work and in the cited papers. For the angles 55, 78, and 94° the data on  $P_3(\vartheta_3)$  were taken from<sup>12,13,1</sup>, in which the experimental conditions were close to ours.

We determined simultaneously the two parameters  $A$  and  $P_2$ . The values of these parameters for pn scat-

the assumptions made concerning the meson-production mechanism. In this connection, the uniqueness problem possibly requires additional investigations.

Table II lists the phase-shift sets II and III after their refinement using the results of the present paper.

The authors take pleasure in thanking G. D. Stoletov for help in producing the longitudinally polarized beam, I. Bystricky and F. Lehar for supplying individual programs on the data reduction, M. R. Khayatov for help with the measurements, and V. M. Sakovskiy, S. F. Pushkin, V. A. Maksimov, T. I. Smirnov and T. D. Timofeev for tremendous work performed in the spark-chamber photograph reduction.
